Abstract

Currie and Saari initiated the study of least periods of infinite words, and they showed that every integer $n \geq 1$ is a least period of the Thue-Morse sequence. We generalize this result to show that the characteristic sequence of least periods of a k -automatic sequence is (effectively) k -automatic. Through an implementation of our construction, we confirm the result of Currie and Saari, and we obtain similar results for the period-doubling sequence, the Rudin-Shapiro sequence, and the paperfolding sequence.

1 Introduction

In a recent paper, Currie and Saari [5] initiated the study of the least periods of infinite words. If $x = a_1 \cdots a_n$ is a finite word, then we say x has period $p \geq 1$ if $a_i = a_{i+p}$ for $1 \leq i \leq n - p$. For example, **alfalfa** has period 3 and **entanglement** has period 9. If $\mathbf{x} = a_0 a_1 a_2 \cdots$ is an infinite word, then a *factor* of $\mathbf{x}$ is a contiguous subword of the form $a_i a_{i+1} \cdots a_j$ for some i, j with $0 \leq i \leq j + 1$; we write it as $\mathbf{x}[i..j]$. (If $i = j + 1$ then the factor is ϵ , the empty string.)

Currie and Saari were interested in the set of all positive integers that can be the least period of some finite nonempty factor of $\mathbf{x}$. They explicitly computed the set of least periods for some famous infinite words, such as the Thue-Morse sequence.

The Thue-Morse sequence $\mathbf{t} = 0110100110010110 \cdots$ is defined by letting $\mathbf{t}[n]$ be the sum of the bits in the binary expansion of n , taken modulo 2. They proved that every positive integer can be the least period of the Thue-Morse sequence.

The Thue-Morse sequence is one of a much larger class of infinite words called “automatic”. Roughly speaking, an infinite word $\mathbf{x}$ is k -automatic if there is a deterministic finite

automaton taking the base- k representation of n as input, with transitions leading to a state with output $\mathbf{x}[n]$. For more details, see [4, 2].

In this note, we prove that if $\mathbf{x}$ is k -automatic, then so is the characteristic sequence of the least periods of $\mathbf{x}$. Our method gives an explicit way to construct the automaton accepting the base- k representation of the least periods of $\mathbf{x}$. Using an implementation developed by the first author, we then reprove the Currie-Saari result for Thue-Morse using a short finite computation, and we find similar results for three other classic sequences.

2 The main result

Theorem 1. *If $\mathbf{x}$ is a k -automatic sequence, then the characteristic sequence of least periods of $\mathbf{x}$ is (effectively) k -automatic.*

Proof. Using the method developed in [1, 3], it suffices to construct a predicate $L(n)$ that is true if n is a least period and false otherwise, using a logical language restricted to addition, subtraction, indexing into $\mathbf{x}$, comparisons, logical operations, and the existential and universal quantifiers.

It is easy to express the predicate P that n is a period of the factor $\mathbf{x}[i..j]$, as follows:

$$\begin{aligned} P(n, i, j) &= \mathbf{x}[i..j - n] = \mathbf{x}[i + n..j] \\ &= \forall t \text{ with } i \leq t \leq j - n \text{ we have } \mathbf{x}[t] = \mathbf{x}[t + n]. \end{aligned}$$

Using this, we can express the predicate LP that n is the least period of $\mathbf{x}[i..j]$:

$$LP(n, i, j) = P(n, i, j) \text{ and } \forall n' < n \neg P(n', i, j).$$

Finally, we can express the predicate that n is a least period as follows

$$L(n) = \exists i, j \geq 0 \text{ with } 0 \leq i + n \leq j - 1 \text{ } LP(n, i, j).$$

The construction is effective, and there is an algorithm that, given the automaton generating $\mathbf{x}$, will produce an automaton generating the characteristic sequence of least periods of $\mathbf{x}$. $\square$

3 Computations

Currie and Saari [5, Thm. 2] proved

Theorem 2. *For each integer $n \geq 1$, the Thue-Morse word has a factor of period n .*

We implemented the algorithm in [6] to convert the automaton generating a k -automatic sequence $\mathbf{x}$ to the automaton accepting the characteristic sequence of least periods of $\mathbf{x}$. Using this, we were able to verify the result above using a short computation. (In contrast, Currie and Saari used four pages of rather intricate case reasoning.)

We also carried out the same computation for three other famous infinite words:

- The period-doubling sequence $\mathbf{d} = d_0 d_1 \dots$ defined by $d_n = 1$ if $\mathbf{t}[n] \neq \mathbf{t}[n+1]$, and 0 otherwise;
- The paperfolding sequence $\mathbf{p}$, defined as the limit of the finite words $p_0 = 0$ and $p_{i+1} = p_i 0 \overline{p_i^R}$, where $\overline{0} = 1$, $\overline{1} = 0$, and w^R denotes the mirror image or reversal of the word w ;
- The Rudin-Shapiro sequence $\mathbf{r} = r_0 r_1 \dots$ defined by counting the number of (possibly overlapping) occurrences of 11 in the binary representation of n , taken modulo 2.

Our results can be summarized as follows:

Theorem 3. *For each integer $n \geq 1$, the period-doubling sequence and the Rudin-Shapiro sequence have a factor of least period n .*

For the paperfolding sequence, the least periods are given by the integers whose base-2 representations are accepted by the automaton below. The least omitted least period is 18, and there are infinitely many. In the limit, exactly 57/64 of all integers are least periods of the paperfolding sequence.

Figure 1: A finite automaton accepting least periods of the paperfolding sequence

Proof. The first results were obtained through our algorithm. A summary of our computations appears below:

Sequence name	Number of states in largest intermediate automaton	Number of states in final automaton	Seconds of CPU time
Thue-Morse	264	1	5.882
Rudin-Shapiro	1029	1	27.797
Period-doubling	89	1	4.327
Paper-folding	393	12	11.597

For the result about the paperfolding sequence, we take the automaton computed by the algorithm (displayed in Figure 1) and compute the transition matrices M_a , $a \in \{0, 1\}$, containing a 1 in row i and column j if there is a transition on a from state i to state j . Then $(M^n)_{i,j}$, where $M := M_0 + M_1$, gives the number of words taking the automaton from state i to state j . A short computation gives that each row of $\lim_{n \rightarrow \infty} 2^{-n} M^n$ equals

$$\frac{1}{64}[0, 16, 8, 4, 2, 10, 5, 4, 4, 2, 6, 3].$$

All states except 7 and 11 are accepting, so the density of least periods is given by $(64 - 4 - 3)/64 = 57/64$, as claimed. $\square$
